Bose-Einstein condensation (BEC) of composite diquarks in quark matter (the color superconductor phase) is discussed using the quasi-chemical equilibrium theory at a relatively low density region near the deconfinement phase transition, where dynamical quark-pair fluctuations are assumed to be described as bosonic degrees of freedom (diquarks). A general formulation is given for the diquark formation and particle-antiparticle pair-creation processes in the relativistic framework, and some interesting properties are shown, which are characteristic for the relativistic many-body system. Behaviors of transition temperature and phase diagram of the quark-diquark matter are generally presented in model parameter space, and their asymptotic behaviors are also discussed. As an application to the color superconductivity, the transition temperatures and the quark and diquark density profiles are calculated in case with constituent/current quarks, where the diquark is in bound/resonant state. We obtained $T_C \sim 60-80\,\mathrm{MeV}$ for constituent quarks and $T_C \sim 130\,\mathrm{MeV}$ for current quarks at a moderate density ($\rho_b \sim 3\rho_0$). The method is also developed to include interdiquark interactions into the quasi-chemical equilibrium theory within a mean-field approximation, and it is found that a possible repulsive diquark-diquark interaction lowers the transition temperature by $\sim 50\,\%$.

I. INTRODUCTION

Several arguments based on the quantum chromodynamics (QCD) show that the hadronic matter makes transition from the hadron phase to the quark-gluon one at sufficiently high temperature and/or large baryon-number density. In particular, recent intensive studies on the quark matter suggest that, in low temperature, it becomes a condensed state of quark pairs called the color superconductor (CSC), where the color $SU(3)$ symmetry is spontaneously broken [1, 2, 3]. In model calculations, the most attractive quark-quark interaction induced by gluon exchange appears in the total spin singlet ($J = 0$) and the color anti-triplet ($\bar{\mathbf{3}}$) channel, so that the CSC phase is considered to be a state where the quark pairs with these quantum numbers are condensed coherently in a similar mechanism with the BCS theory [4].

Generally, there exist two limiting cases in the fermion-pair condensation: weak- and strong-coupling regions in the strength of the two-fermion correlation. In the weak-coupling region, which appears in the high-density quark matter because of the asymptotic-freedom of QCD [5], the coherence length ξ becomes larger than the interquark distance d, and the quark matter becomes the weakly-interacting fermion system where the mean-field picture are applicable. The strong-coupling region appears in the moderate- or low-density quark matter (especially in the neighbor of the deconfinement transition point). Large pair-fluctuations develop [6] and the coherence length is suggested to be very small; $\xi/d \sim O(1-10)$, even around the moderate-density region [$\sim O(10)\rho_0$] from the analysis of the improved ladder approximation [7]. This implies that, for low-density region [$\sim O(1)\rho_0$], $\xi/d \ll 1$ and the strong quark-pair correlations are described by bosonic degrees of freedom, which we call “diquark” in this paper. Thus, for the description of this diquark region of the quark matter, the incorporation of two-particle correlations beyond mean-field levels is essentially important.

Several methods have been proposed to incorporate the correlation effects. A typical one is that of Nozières and Schmitt-Rink, where thermodynamic potentials are calculated in the normal phase using the in-medium ladder approximation, and the fermion number density is shown to include a contribution

from the bosonic part through the two-body in-medium scatterings [8, 9]. The transition temperature is obtained from the zero-frequency pole of the two-particle correlation function (Thouless criterion for second-order phase transitions).

The quasi-chemical equilibrium theory is an another approach developed by Schafroth, Butler, and Blatt [10] for the fermion-pair condensates. Using a cluster expansion technique for the partition function, the fermion-pair condensates are shown to be in chemical equilibrium states between the isolated fermions and the bosonic difermions identified with the in-medium resonant/bound states of two fermions. This method was firstly invented to describe the experimental phenomena of electric superconductivity of metals in 1940', before the birth of BCS theory. In modern sense, this quasi-chemical equilibrium picture corresponds to the strong coupling superconductor ($\xi/d \leq 1$), and the transition temperature, which is obtained as the BEC-T_C of difermions under the equilibrium, is shown to be equivalent with that in Nozières-Schmitt-Rink theory in the strong-coupling limit ($\xi/d \ll 1$).

In the strong-coupling region of the quark matter, we can expect that the similar quark-pair fluctuations develop and the CSC is described by the diquark condensate in equilibrium with isolated quarks.

The diquark correlation effects have been proposed by Jaffe and Low [13, 14] in relation with the phenomenology of the low-energy hadron-hadron collisions and the multi-hadron spectroscopy. Also, roles of composite diquarks in the quark-gluon plasma have been studied by Ekelin, et al. [23, 24], especially for the hadronization process in the high-energy e^+e^- collision; they considered the space-time developments of the quark-gluon plasma as an adiabatic process, and discussed the possibility of the diquark BEC rather at high-T stages in that process. Also the diquark correlations have been discussed to study the stability of diquark matter but without regard to diquark BEC [25, 26, 27, 28, 29].

In this paper, we make a general formulation of the quasi-chemical equilibrium theory for the relativistic many-fermion system, and apply it to the strong-coupling quark matter with composite diquarks. Our special interest is on diquark BEC that should be the CSC in the strong-coupling region, and we clarify the CSC states as diquark BEC at finite temperature and density within the quasi-equilibrium theory in less model-dependent way. In Sec. II, we formulate the quasi-chemical equilibrium theory for the difermion formation and the particle-antiparticle pair-creation processes in the relativistic many-body system. We also show some interesting properties for the BEC of difermions which are characteristic in the relativistic system. In Sec. III, applying the method to the quark-diquark matter, we show T_C of the diquark BEC, a phase diagram on quark/diquark masses, and asymptotic behaviors of them. We also discuss T_C of the color superconductor using phenomenological values of parameters. In Sec. IV, effects of the interdiquark interactions are discussed in a mean-field approximation. Sec. V is devoted to summary and outlook. Throughout this paper, we use the natural units: $c = \hbar = k_B = 1$.

II. RELATIVISTIC QUASI-CHEMICAL EQUILIBRIUM THEORY

A. Molecular formation/annihilation process

To develop the quasi-chemical equilibrium theory, we consider molecular formation/annihilation process in a fermionic matter:

$$F_1 + F_2 \longleftrightarrow (F_1 F_2) = B, \tag{1}$$

where $F_{1,2}$ are fermions with masses $m_F \equiv m_{F_1} = m_{F_2}$, and B is a composite boson of F_1 and F_2 with mass m_B; the composite boson B should be a bound state ($m_B < 2m_F$) or a resonance state ($m_B > 2m_F$). We call it "molecule" in both cases.

Here we take the quasi-particle picture for the fermionic matter where the system consists of quasi-fermions (F_1 and F_2) and quasi-bosons (B). The two-body interactions between fermions bring about the two-body correlations in the matter; their major effects are for the binding/resonance energy of the composite boson B and the residual interactions among quasi-particles. This quasi-particle interactions are generally regarded to be weak, and we neglect it in the first part of this paper. In Sec. IV, we introduce the quasi-particle interactions and discuss their effects within a mean-field approximation.

The equilibrium condition for the process (1) is given by

$$\mu_{F_1} + \mu_{F_2} = \mu_B, \tag{2}$$

where $\mu_{F_1,F_2,B}$ are the chemical potentials of the particles F_1, F_2 and B, which should be functions of the temperature T and the particle-number densities $n_{F_1,F_2,B}$. For free uniform gases, they are given by the Bose/Fermi statistics:

$$n_B = \frac{1}{(2\pi)^3}\int \frac{d^3\mathbf{k}}{e^{\beta(\varepsilon_B-\mu_B)}-1}, \tag{3}$$

$$n_{F_\alpha} = \frac{1}{(2\pi)^3}\int \frac{d^3\mathbf{k}}{e^{\beta(\varepsilon_{F_\alpha}-\mu_{F_\alpha})}+1}, \quad (\alpha = 1,2) \tag{4}$$

where $\beta = 1/T$. Using the relativistic energy-momentum dispersion relations: $\varepsilon_a = \sqrt{m_a^2 + \mathbf{k}^2}$ ($a = F_1, F_2, B$), eqs. (3,4) become

$$n_B = \frac{1}{2\pi^2}\int_{m_B}^{\infty} \frac{\varepsilon\sqrt{\varepsilon^2 - m_B^2}}{e^{\beta(\varepsilon-\mu_B)}-1}d\varepsilon \equiv m_B^3 B_R(-\beta\mu_B, m_B\beta), \tag{5}$$

$$n_{F_\alpha} = \frac{1}{2\pi^2}\int_{m_{F_\alpha}}^{\infty} \frac{\varepsilon\sqrt{\varepsilon^2 - m_{F_\alpha}^2}}{e^{\beta(\varepsilon-\mu_{F_\alpha})}+1}d\varepsilon \equiv m_{F_\alpha}^3 F_R(-\beta\mu_{F_\alpha}, m_{F_\alpha}\beta), \qquad (\alpha = 1,2) \tag{6}$$

In the above equations, the relativistic Bose/Fermi functions B_R and F_R are defined by

$$B_R(\nu,\tilde{\beta}) = \frac{1}{2\pi^2}\int_1^{\infty} \frac{\tilde{\varepsilon}\sqrt{\tilde{\varepsilon}^2-1}}{e^{\tilde{\beta}\tilde{\varepsilon}+\nu}-1}d\tilde{\varepsilon} = \frac{1}{2\pi^2}\int_0^{\infty}\frac{\cosh\theta(\sinh\theta)^2}{e^{\tilde{\beta}\cosh\theta+\nu}-1}d\theta, \tag{7}$$

$$F_R(\nu,\tilde{\beta}) = \frac{1}{2\pi^2}\int_1^{\infty} \frac{\tilde{\varepsilon}\sqrt{\tilde{\varepsilon}^2-1}}{e^{\tilde{\beta}\tilde{\varepsilon}+\nu}+1}d\tilde{\varepsilon} = \frac{1}{2\pi^2}\int_0^{\infty}\frac{\cosh\theta(\sinh\theta)^2}{e^{\tilde{\beta}\cosh\theta+\nu}+1}d\theta, \tag{8}$$

where we use scaled variables $\tilde{\beta} = m\beta$ and $\tilde{\varepsilon} = \varepsilon/m$, and the Jüttner variable θ that is defined by $\tilde{\varepsilon} = \cosh\theta$ [30, 31].

The boson chemical potential μ_B satisfies $\mu_B \leq m_B$ from the positive norm condition of n_B, and the boson density (5) has a singularity at this upper bound, where a phase transition occurs to the Bose-Einstein condensate. In the BEC region ($\mu_B = m_B$), the boson density consists of the condensed and thermal parts, $n_B = n_B^{(0)} + n_B^{(th)}$, which are given by $n_B^{(th)} = m_B^3 B_R(-\beta m_B, m_B\beta)$ and $n_B^{(0)} = n_B - n_B^{(th)}$ [32].

In the process (1), the particle-number conservations for $F_{1,2}$ give constraints for the densities:

$$n_{F_1} + n_B = n_{F_1,t}, \qquad n_{F_2} + n_B = n_{F_2,t}, \tag{9}$$

where $n_{F_{1,2},t}$ are the total number densities of $F_{1,2}$, which consist of isolated fermions and those included in the composite boson B.

Solving eqs. (2) and (9) with (5,6), we can obtain the densities n_{B,F_1,F_2} in equilibrium at temperature T.

B. Particle-antiparticle pair-creation/annihilation process

The energy scale in the quark-diquark system is so large that the antiparticle degrees of freedom are generally important. Here we develop the quasi-chemical equilibrium theory for the particle-antiparticle system.

The fermion-antifermion (quark-antiquark) or boson-antiboson (diquark-antidiquark) pairs can be created through the radiation process mediated by the gauge boson (gluon);

$$G \longleftrightarrow P + \bar{P}, \qquad (P = F_1, F_2, B) \tag{10}$$

Thus the equilibrium condition for the above process is given by $\mu_P + \mu_{\bar{P}} = \mu_G$, where $\mu_{P,\bar{P},G}$ are the chemical potentials of the particle P, the antiparticle $\bar{P}$ and the gluon G. We put $\mu_G = 0$ because the gluon is a massless particle, so that the chemical potentials of P and $\bar{P}$ have a relation: $\mu_{\bar{P}} = -\mu_P$.

In the process (10), the difference between the particle and antiparticle densities should be conserved:

$$n_{b,P} = n_P - n_{\bar{P}}, \qquad (P = F_1, F_2, B) \tag{11}$$

where $n_{b,P}$ corresponds to the baryon-number density of quark or diquark degrees of freedom. As given in (5,6), the boson/fermion number-densities of the particle and antiparticle at the temperature T are given by

$$\begin{aligned} n_B &= m_B^3 B_R(-\beta\mu_B, m_B\beta), & n_{\bar{B}} &= m_B^3 B_R(\beta\mu_B, m_B\beta), & & (12)\\ n_{F_\alpha} &= m_{F_\alpha}^3 F_R(-\beta\mu_{F_\alpha}, m_{F_\alpha}\beta), & n_{\bar{F}_\alpha} &= m_{F_\alpha}^3 F_R(\beta\mu_{F_\alpha}, m_{F_\alpha}\beta), & (\alpha = 1,2) & \quad (13)\end{aligned}$$

where B_R and F_R have been defined in (7,8).

Eq. (5) shows that the boson chemical potentials are found to have the upper bound; $\mu_{B,\bar{B}} \le m_B$. From the relation $\mu_B = -\mu_{\bar{B}}$, they are also found to have the lower bound:

$$-m_B \le \mu_{B,\bar{B}} \le m_B, \tag{14}$$

where $\mu_B \ge 0$ ($\mu_B \le 0$) corresponds to $n_{b,B} = n_B - n_{\bar{B}} \ge 0$ ($n_{b,B} \le 0$). Furthermore, the upper and lower bounds of μ_B in (14) correspond to the boson BEC ($\mu_B = m_B$) and antiboson BEC ($\mu_{\bar{B}} = m_B$) respectively, which means that bosons and antibosons cannot be condensed to the BEC state at the same time in equilibrium states.

The transition temperature T_C of the boson BEC (the antiboson BEC) is determined by (11) with $\mu_B = m_B$ ($\mu_B = -m_B$):

$$n_{b,B} = [n_B - n_{\bar{B}}]_{\mu_B = \pm m_B, T=T_C}. \tag{15}$$

C. Molecular formation/annihilation processes of many kinds of particles

Here we consider a general system of many kinds of fermions F_α and molecular bosons B_β which are bound/resonant states of two fermions. The fermions are assumed to be transmuted through some processes; $F_\alpha \leftrightarrow F_{\alpha'}$. As is same with the previous simple case, the total number density of fermions $n_{F,t}$ is to be conserved in molecular formation/annihilation process of B_β, and is given by summing all species of fermions $n_{F_\alpha,t}$, which also amounts to summation of isolated fermions n_{F_α} and those included in composite bosons n_{B_β}:

$$n_{F,t} \equiv \sum_\alpha n_{F_\alpha,t} = \sum_\alpha n_{F_\alpha} + 2\sum_\beta n_{B_\beta}. \tag{16}$$

To obtain the equilibrium condition for the above condition, we take the Helmholtz free-energy density of the system:

$$\begin{aligned} f &\equiv F/V = f_{T,V} + \sum_\alpha \mu_{F_\alpha} n_{F_\alpha} + \sum_\beta \mu_{B_\beta} n_{B_\beta} \\ &\quad + K\left(n_{F,t} - \sum_\alpha n_{F_\alpha} - 2\sum_\beta n_{B_\beta}\right), \end{aligned} \tag{17}$$

where $f_{T,V}$ is the density-independent part, and the last term has been added to expose the constraint (16) with the Lagrange multiplier K. Differentiating eq. (17) with respect to n_{F_α} and n_{B_β}, one obtains for $^\forall\alpha, ^\forall\beta$

$$2\mu_{F_\alpha} = 2K = \mu_{B_\beta}. \tag{18}$$

This means that the chemical potentials of fermions and bosons take the same values μ_F and μ_B in an equilibrium state, which obey the condition (2); $2\mu_F = \mu_B$.

The range of the chemical potential is $\mu_B = \mu_{B_\beta} \le m_{B_\beta}$ for any B_β and, without loss of generality, the boson B_1 is assumed to be the one with the smallest mass (most-stable composite); $m_{B_1} < m_{B_{\beta\ne1}}$. Then, the range of μ_B becomes

$$\mu_B (= 2\mu_F) \le m_{B_1}. \tag{19}$$

It shows that, at the upper bound of the chemical potential ($\mu_{B_1} = \mu_B = m_{B_1}$), the BEC occurs for the boson B_1, but there exists no BEC singularity for the other bosons because $\mu_{B_{\beta\ne1}} = \mu_B = m_{B_1} < m_{B_\beta}$.

In summary, the BEC occurs only for the boson with the smallest mass below the transition temperature T_C, and the other bosons with larger masses (less-stable composites) cannot be condensed to the BEC states at any temperature and density (one-BEC theorem).

The critical temperature T_C for the B_1's BEC can be determined from the condition at $T = T_C$:

$$\left[\sum_{\alpha} n_{F_\alpha} + 2\sum_{\beta} n_{B_\beta}\right]_{2\mu_F=\mu_B\to m_{B_1}} = n_{Ft}. \tag{20}$$

Below T_C, the density of B_1 consists of the thermal and condensed parts:

$$n_{B_1}^{(th)} = m_{B_1}^3 B_R(-\beta m_{B_1}, m_{B_1}\beta), \tag{21}$$

$$n_{B_1}^{(0)} = \frac{1}{2}\left[n_{F,t} - \sum_{\alpha} n_{F_\alpha} - 2\sum_{\beta\neq 1} n_{B_\beta}\right] - n_{B_1}^{(th)}, \tag{22}$$

where $n_{F,t} = \sum_\alpha n_{F_\alpha,t}$ is the total fermion number, and n_{B_β,F_α} are given by (12,13) again.

In the case of the system with antiparticle degrees of freedom, antibosons cannot be condensed to BEC state if the baryon-number density is positive. This can be also understood by one-BEC theorem. The ground state contributions of bosons (B_1) and antibosons ($\bar{B}_1$) are explicitly given by

$$n_{B_1}^{(0)} = \frac{1}{V}\frac{1}{e^{\beta(m_{B_1}-\mu_B)}-1}, \tag{23}$$

$$n_{\bar{B}_1}^{(0)} = \frac{1}{V}\frac{1}{e^{\beta(m_{B_1}+\mu_B)}-1} = \frac{1}{V}\frac{1}{e^{\beta((m_{B_1}+2\mu_B)-\mu_B)}-1}, \tag{24}$$

which means that the antiboson is effectively heavier than boson by $2\mu_B(>0)$ and BEC occurs only for bosons B_1 by using one-BEC theorem (In case that the baryon-number density is negative, $\mu_B < 0$, only $\bar{B}_1$ can then be condensed to BEC state at the lower bound $\mu_B = -m_{B_1}$).

III. DIQUARK BOSE-EINSTEIN CONDENSATION IN QCD

In this section, we apply the relativistic quasi-chemical equilibrium theory developed in the previous section to the color superconductivity of quark matter in BCS-BEC crossover regime [11, 12], where quark-pair fluctuations develop dynamically to create diquarks (composite bosons). A possibility of quark-quark correlations has also been suggested in low-energy hadron physics [13, 14], and its extrapolation to the deconfinement phase can be considered to become diquark degrees of freedom in dense region [25, 28, 29].

A. Applicability of quasi-chemical equilibrium theory for quark matter

Before going to actual calculations we should evaluate the applicability of quasi-chemical equilibrium theory for interacting fermionic systems, which was originally discussed by Schafroth, et al. with respect to electron gas in superconducting metals [10]:

1) particles of compositions (fermions F and composite molecules B) should be quasi-particles,

2) correlations between FB and BB are unimportant,

3) higher-order correlations are not stronger than the pair-correlations considered,

4) any localizations to liquid droplets with large volume exclusion (gas-liquid transition) do not occur before the formation of quasi-molecules,

5) composites sufficiently obey the Bose statistics as expected with small size of composites relative to the interparticle distance.

Now we discuss the condition 1) for quark matter. The lifetime of a particle relates to various decay processes in medium, and to recognize quark as quasi-particle its lifetime should be at least longer than inverse of the QCD energy scale, that is, $O(1)$ fm. The lifetime of quarks tends to be shorter near the Fermi surface, which can be roughly estimated from the imaginary part of quark self-energy, e.g., [15]; $\tau \sim 30^{-1}$ MeV^{-1}. In our model these quarks with short lifetime near Fermi surface due to strong pair fluctuations are described as bosonic molecules, and residual quarks in the deeper interior of the Fermi sphere have explicitly longer lifetime than the QCD scale. Thus, quarks (antiquarks) being outside of pairs due to medium effects can be identified as quasi-particles. As for the diquark composites, its lifetime as quasi-particle is expected to be longer than that of quarks in crossover regime, as Shuryak and Zahed suggested the existence of various binary bound states in the whole regions just above the deconfinement temperature because QCD coupling strength is found not to be so small as one has believed so far [16]. Thus, diquarks should also be identified in medium.

Concerning other conditions 2) and 3), higher-order correlations rather than pair ones are not treated in this Sec. III. This treatment corresponds to the Gaussian-type approximations like Nozières and Schmitt-Rink approach [8, 9, 12]. The effects of higher-order correlations, especially interdiquark interactions, will be discussed in Sec. IV with sincere generalization of quasi-chemical equilibrium theory. Condition 4) is also discussed in the end of Sec. IV.

With regard to condition 5), the density dependence of coherence length ξ, characterising typical size of a Cooper pair, relative to interquark distance d is estimated by using the improved ladder approximation [7], which suggests that $\xi/d \leq 1$ for $\rho_b < 10\rho_0$. This means that $\xi/d \ll 1$ for lower density region $\rho_b \sim 3\rho_0$ concerned, and our quasi-chemical equilibrium approach with bosonic modes is expected to work well for these strong couplig regimes of quark matter.

The critical coupling strength for the formation of diquark bound states is also calculated by using effective four-Fermi interaction model with Gaussian approximation [12], and critical value $G/(\pi^2/\Lambda^2) \simeq 0.92$ (Λ is ultraviolet cutoff scale) and its relavance for real quark matter is suggested therein. Because of smooth crossover, this critical value of coupling strength corresponding to the unitary limit in cold atomic systems brings no sudden changes for physical quantities. The essential quantity for the behavior of BEC-BCS crossover is always the ratio of the coherence length to the interparticle distance.

Although above quantitative argumets come from some specific model calculations, recent analyses on QCD experiments, e.g., relativistic heavy ion collision [17] and lattice QCD [18], also suggest that even in deconfinement phase QCD holds strong coupling at almost whole region of the phase diagram relevant to possible observations. We expect that our present approach works well in such strong coupling regimes in more general way, especially around the region close to the phase transition line where correlations between quarks should develop largely and the strong coupling picture becomes essential for the pairing problem. In this context three-quark correlations in addition to pairing will be important issue around this region, which can also be treated in our approach.

Here we comment on the BEC-BCS crossover in beta-equilibriated charge-neutral quark matter, where mismatches of Fermi surfaces exist in different flavors. Even in the weak coupling regime, various phases have been proposed in that matter in relation with the chromomagnetic instability problem: the gapless superconductor [19], the crystalline color superconductor [20], the gluon condensed state [21], and so on. The strong coupling limit has also been discussed of the two-flavor quark matter with Fermi-surface mismatch [22]. These considerations suggest that the Cooper-pair formation should still be favored in the case if the energy gain by the pairing exceeds the energy differences of the mismatched Fermi surfaces. Thus we can expect the crossover into the diquark BEC in the quark matter with finite mismatches for sufficiently large coupling strength and, at the temperature around T_C, the mismatch effects are expected to be small with large pairing energy. In low temperature region, however, the Fermi-surface mismatches makes the unpaired fermions remain with some flavor, and they should form new Fermi surfaces; the calculation of the profile changes of them around the crossover region should be a very interesting problem in future.

In the present paper, we take the two-flavor quark matter with same Fermi surfaces to discuss typical features of diquark BEC; however, our approach can be extended to the case of the finite Fermi- surface mismatches and their effects in the diquark BEC and crossover will be discussed in another paper.

B. Baryon-number conservation and chemical equilibrium condition

In what follows, we take u,d-quark matter around the moderate density region in QCD, and consider the chemical equilibrium between quarks and composite diquarks in the 2SC-type pairing state (color antisymmetric $\bar{\mathbf{3}}$, flavor antisymmetric, and total-spin $J = 0$) [1, 2, 3]. The other types of diquarks can also be created in the quark matter using less attractive channels, e.g., diquarks in color-$\bar{\mathbf{3}}$, flavor symmetric and the $J = 1$ pairing state [33, 34]. But, according to the one-BEC theorem derived in the previous section, the diquark BEC can occur only for the smallest mass (most stable) diquark, i.e. in the 2SC-diquark state of u and d quarks, so that we consider only the 2SC-diquarks. Generally the diquarks which do not participate in the BEC would have the effect of lowering the critical temperature, through the total-number conservation, in comparison with the case of one kind of diquark. We also assume that the quark and diquark masses do not depend on the temperature and density, but the present formalism is also applicable to the case with effective masses dependent on these parameters.

In the quark-diquark matter, the baryon-number density $\rho_b (\equiv n_b/3)$ corresponds to the conserved total fermion-number density $n_{F,t}$ in (11) or (16), where n_b is the regularized baryon-number density in quark degrees. In the chemical equilibrium between quarks and 2SC-diquarks, it is given by

$$n_b = 3 \cdot 2 \cdot 2 \cdot (n_q - n_{\bar{q}}) + 2 \cdot 3 \cdot 1 \cdot 1 \cdot (n_d - n_{\bar{d}}) \,, \tag{25}$$

where $n_{q,\bar{q}}$ are the number densities of quark and antiquark, and $n_{d,\bar{d}}$ are those of diquark and antidiquark. The numerical factors in (25) come from the degeneracy of the internal degrees of freedom: the color-triplet (3), the flavor-doublet (2), the spin-doublet (2) for the quark-density term, and the compositeness (2), the color-anti-triplet (3), the flavor-singlet (1), the spin-singlet (1) for the diquark-density term.

Eqs. (12,13) gives the densities $n_{q,\bar{q}}$ and $n_{d,\bar{d}}$ in equilibrium at temperature T:

$$n_q = m_q^3 F_R(-\beta\mu_q, m_q\beta), \qquad n_{\bar{q}} = m_q^3 F_R(\beta\mu_q, m_q\beta), \tag{26}$$

$$n_d = m_d^3 B_R(-\beta\mu_d, m_d\beta), \qquad n_{\bar{d}} = m_d^3 B_R(\beta\mu_d, m_d\beta), \tag{27}$$

where $m_{q,d}$ are a quark/antiquark and a diquark/antidiquark masses, and $\mu_{\bar{P}} = -\mu_P$ ($P = q, d$) has been used for the chemical potentials of antiquark and antidiquark. When the diquark (antidiquark) BEC occurs for $T \leq T_C$, the diquark (antidiquark) density consists of the condensed and thermal parts: $n_d = n_d^{(0)} + n_d^{(th)}$ ($n_{\bar{d}} = n_{\bar{d}}^{(0)} + n_{\bar{d}}^{(th)}$), which are obtained in the same way as eqs. (21,22). Especially these condensates $n_d^{(0)}$ and $n_{\bar{d}}^{(0)}$ are the superfluid density of CSC. If the baryon-number density is positive, diquark BEC can only be expected as mentioned in the previous section.

The chemical potentials μ_q and μ_d should obey the quark-diquark equilibrium condition:

$$2\mu_q = \mu_d, \tag{28}$$

which corresponds to (2). The set of eqs. (25-28) determines a composition of the baryon-number density in the quark-diquark quasi-chemical equilibrium system.

C. Transition temperature of quark-diquark system

As shown in the previous section, diquark BEC occurs when the diquark chemical potential reaches the upper limit $\mu_d = m_d$. In the quark-diquark system considered here, the conditions for T_C are

$$2\mu_q = \mu_d = m_d, \tag{29}$$

$$n_b = \Big[3 \cdot 2 \cdot 2 \cdot (n_q - n_{\bar{q}}) + 2 \cdot 3 \cdot 1 \cdot 1 \cdot (n_d^{(th)} - n_{\bar{d}}^{(th)}) \Big]_{T=T_C} \,, \tag{30}$$

where we have used eqs. (25,28). For any fixed values of the quark and diquark masses $m_{q,d}$, and for the baryon-number density n_b in (30), T_C is obtained by solving these equations.

Fig. 1 shows dependence of T_C on $2m_q$ and m_d for the baryon-number densities $\rho_b = 2\rho_0, 3\rho_0, 4\rho_0$ where $\rho_0 \sim 1.3 \times 10^6\,\mathrm{MeV}^3$ is the normal nuclear density. These figures show that T_C increases with the baryon-number density; especially it can be read from the shrinkage of no-BEC region (area in the front side in the ($2m_q$,m_d)-plane). This effect can be understood that T_C goes up with increase of the diquark density together with the baryon density, as seen in the behavior of T_C in the ideal bose gases (see Appendix A).

These diagrams also show that the large diquark mass has an effect of lowering T_C. It is consistent with the results for one-component boson-antiboson gas (see Appendix B); $T_C \propto m_d^{-1}$ in nonrelativistic limit (A8) and $\propto m_d^{-1/2}$ in ultrarelativistic limit (A17). The increase of T_C for large quark-masses is attributed to the large diquark density brought by the increase in the binding energy ($m_d - 2m_q$).

In the very small mass region of diquark ($m_d \sim 0$), which corresponds to the extremely tight binding case (strong-coupling limit), we find rapid increases of T_C, which is divergent at the massless limit $m_d \to 0$

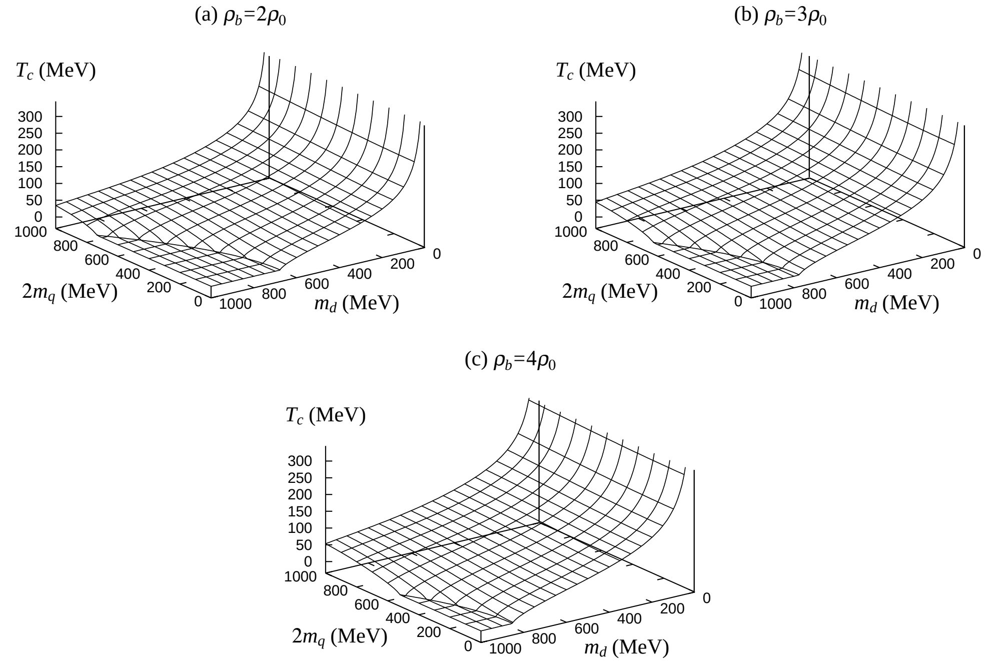

FIG. 1: Transition temperatures T_C of diquark BEC on $(2m_q, m_d)$-plane of quark/diquark masses for the baryon-number densities $\rho_b = 2\rho_0, 3\rho_0, 4\rho_0$ (ρ_0 is the normal nuclear density).

(Fig. 2a). It can be understood from the range (14) and the condition (28) of the chemical potentials, from which we obtain $\mu_q = \mu_d = 0$ in the present limit, meaning that quark and thermal diquark components of the baryon-number densities vanish ($n_q - n_{\bar{q}} = 0$, $n_d^{(th)} - n_{\bar{d}}^{(th)} = 0$) and the conserved baryon-number density is fully compensated by the condensed diquarks ($n_b = 2 \cdot 3 \cdot n_d^{(0)}$) at any temperature (that is, $T_C \to \infty$). This peculiar feature is characteristic of the massless boson with the conserved quantity which is not satisfied by photons, et al.. Quark mass dependences of T_C are shown in Fig. 2b, and we can find

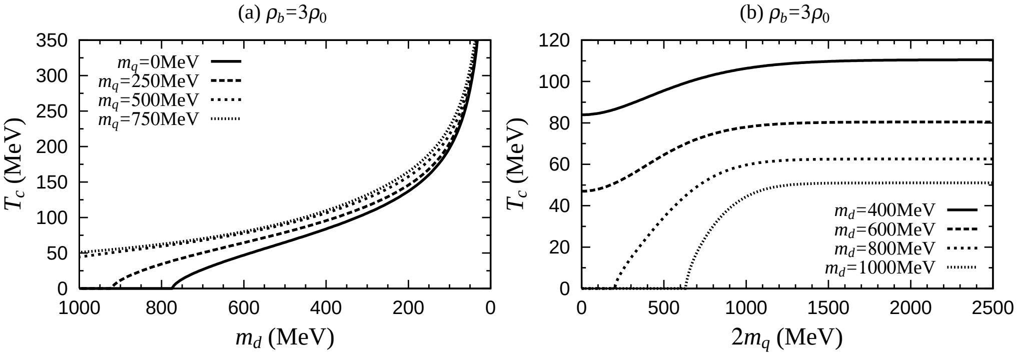

FIG. 2: Transition temperature T_C of diquark BEC: diquark-mass (m_d) dependence (a) and quark-mass (m_q) dependence (b), at $\rho_b = 3\rho_0$. Several lines are for different quark masses $m_q = 0 \sim 750\,\text{MeV}$ (a), and for diquark masses $m_d = 400 \sim 1000\,\text{MeV}$ (b).

that, for large values of m_q, T_C converges into a finite limit that depends on diquark mass m_d: T_C of free bose gas with mass m_d. It is because the quark degrees of freedom are suppressed in the limit of large quark mass.

D. Mass phase diagram of quark-diquark system

In the previous subsection, numerical results (Fig.1) show that there exists the region in $(2m_q, m_d)$-plane where no BEC occurs. In Fig. 3, we plot $T_C = 0$ lines in $(2m_q, m_d)$-plane for several baryon-number densities $\rho_b (= n_b/3)$. This line is the border of the BEC and no-BEC phases (below and above the line), and we call it mass phase diagram, where BEC phase is defined with finite T_C.

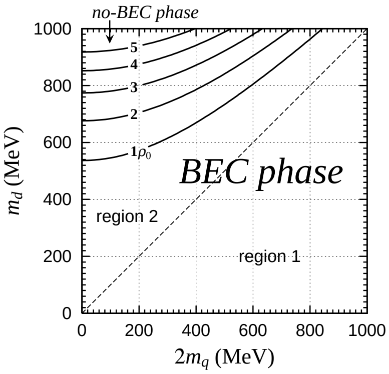

FIG. 3: Mass phase diagram of diquark BEC for $\rho_b = (1 \sim 5)\rho_0$. Curved lines correspond to critical borders between BEC and no-BEC phases. Dashed line is for $2m_q = m_d$, separating region 1 (bound state case ; $m_d < 2m_q$) and region 2 (resonant state case ; $m_d > 2m_q$).

Now we show an analytical derivation of the border in the mass phase diagram by taking the $T_C \to 0$ limit in the formula. At $T = 0$, all antiparticles vanish, so that eq. (25) becomes

$$n_b = [3 \cdot 2 \cdot 2 \cdot n_q + 2 \cdot 3 \cdot 1 \cdot 1 \cdot n_d]_{T \to 0}\,. \tag{31}$$

The diquark density generally consists of the condensed and thermal part $n_d = n_d^{(0)} + n_d^{(th)}$. Just at $T = T_C$, the chemical potential reaches its upper limit $\mu_d = m_d$ but there is still no BEC component, and thermal diquarks are completely frozen in the limit of $T = 0$, so that we obtain $n_d = 0$ at $T = T_C = 0$. The quark density is a monotonously-increasing function of μ_q, and it takes the maximum value at $T = T_C = 0$; $n_q^{\max}$ with $\mu_q = \mu_d/2 = m_d/2$. Thus eq. (31) becomes

$$n_b = 3 \cdot 2 \cdot 2 \cdot n_q^{\max}. \tag{32}$$

From eq. (6), the $n_q^{\max}$ is evaluated to be

$$\begin{aligned} n_q^{\max} &= \left[\frac{1}{2\pi^2} \int_{m_q}^{\infty} \varepsilon \sqrt{\varepsilon^2 - m_q^2} \cdot \theta(\mu_q - \varepsilon) d\varepsilon \right]_{\mu_q = m_d/2} \\ &= \frac{1}{6\pi^2} \left[\left(\frac{m_d}{2} \right)^2 - \left(\frac{2m_q}{2} \right)^2 \right]^{3/2} \times \theta(m_d - 2m_q). \end{aligned} \tag{33}$$

In the case of $m_d < 2m_q$ (region 1 in Fig. 3), the above equation gives $n_q^{\max} = 0$ (no quarks), which leads to the contradictory result of $n_b = 0$ with (32). It means that $T_C > 0$ and all quarks are combined into diquarks with manifest advantage of binding energy and should be condensed to BEC state at $T = 0$ (the BEC phase).

When $m_d > 2m_q$ (region 2 in Fig. 3), eqs. (32,33) gives

$$n_b = \frac{2}{\pi^2} \left[\left(\frac{m_d}{2} \right)^2 - \left(\frac{2m_q}{2} \right)^2 \right]^{3/2}. \tag{34}$$

For the fixed value of n_b, it gives the hyperbolic curve: the border between the BEC and no-BEC phases on $(2m_q, m_d)$-plane as shown in Fig. 3. The behavior of this border is decided by the balance between kinetic energy loss of isolated quarks (Pauli-blocking effect) and resonance energy loss of composite diquarks.

E. Diquark condensations for constituent and current quarks: transition temperature

Now we take a look at proposed values of the quark and diquark masses in quark matter, given by Anselmino, et al. [35], where two kinds of the quark/diquark masses have been presented:

$$\begin{array}{l} \text{case 1} : m_d = 500\,\text{MeV}, \;\; m_q = 200 \sim 300\,\text{MeV}, \\ \text{case 2} : m_d = 200\,\text{MeV}, \;\; m_q = 0 \sim 10\,\text{MeV}. \end{array} \tag{35}$$

The case 1 corresponds to dynamical chiral symmetry breaking which remains even in the deconfinement phase, and thus the large quark mass comes from the, as it were, constituent quarks. Whereas the case 2 is for the chiral restored quark matter with small current quark mass. For the diquark masses, it should be noticed that the diquark is bound ($m_d < 2m_q$) or resonant ($m_d > 2m_q$) states depending on the value of m_q in case 1, but is only the resonant state in case 2. In this paper, we take these two cases for the quark and diquark masses.

Fig. 4 shows dependence of T_C on the baryon-number density in the cases 1 and 2. The larger quark masses get T_C higher because the diquark binding energy ($m_d - 2m_q$) becomes larger. This tendency is less apparent in Fig. 4b compared with Fig. 4a, which is understood that the scale of current quark mass is too small relative to the energy scale of diquark BEC.

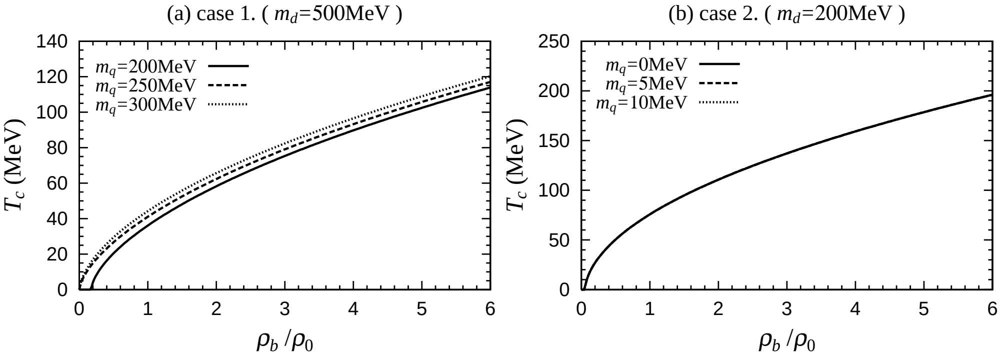

FIG. 4: Baryon-number density (ρ_b) dependences of T_C for case 1 (a) and case 2 (b).

In Fig. 5, comparison for T_C in the nonrelativistic and ultrarelativistic limits is shown in the cases 1 and 2. The analytical representations of T_C in these limits are given by

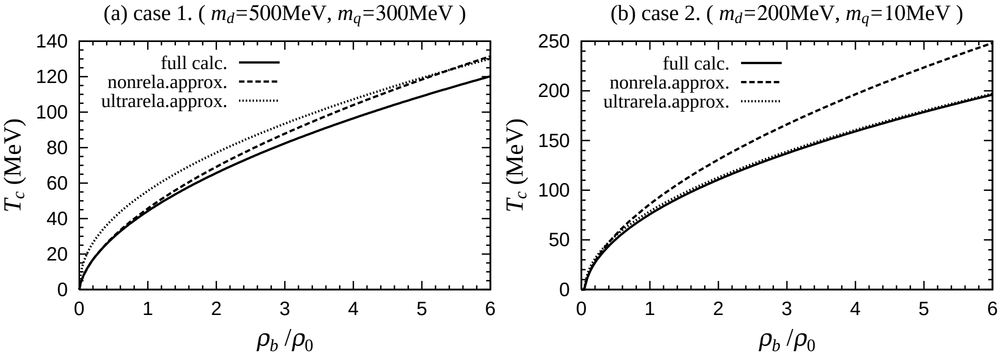

FIG. 5: Baryon-number density (ρ_b) dependences of T_C for case 1 with $(m_d, m_q) = (500, 300)\,\text{MeV}$ (a) and case 2 with $(m_d, m_q) = (200, 10)\,\text{MeV}$ (b), accompanying with T_C in nonrelativistic and ultrarelativistic limits.

$$T_C \sim \begin{cases} 3.313\frac{n_{b,B}^{2/3}}{m_B}, & \text{(nonrelativistic limit)} \\ 1.732\sqrt{\frac{n_{b,B}}{m_B}}. & \text{(ultrarelativistic limit)} \end{cases} \tag{36}$$

The derivation of these formulas are given in Appendix A.

In Fig. 5a (case 1), T_C is found to be approximated by the nonrelativistic formula in lower density region ($\rho_b \lesssim 2\rho_0$), and approaches to the ultrarelativistic one in the high density region; in the intermediate region, the gradual shift is shown between these two limits. It is a typical behavior of the relativistic system. On the other hand, in case 2, the small current quark mass makes the ultrarelativistic approximation valid from the very small density region (Fig. 5b).

F. Diquark condensations for constituent and current quarks: density profiles of quarks and diquarks

Here we discuss the temperature dependences of particle and antiparticle densities shown in Fig. 6 (case 1) and Fig. 7 (case 2) at $\rho_b = 3\rho_0$. The baryon-number density of quark is defined by $\rho_{b,q} = \rho_q - \rho_{\bar{q}}$, and that of diquark consists of the thermal part $\rho_{b,d}^{(th)} = \rho_d^{(th)} - \rho_{\bar{d}}^{(th)}$ and the condensed part $\rho_{b,d}^{(0)} = \rho_d^{(0)}$ (Here we consider only the case of $\rho_b > 0$, so that no condensed antidiquarks exist; $\rho_{\bar{d}}^{(0)} = 0$).

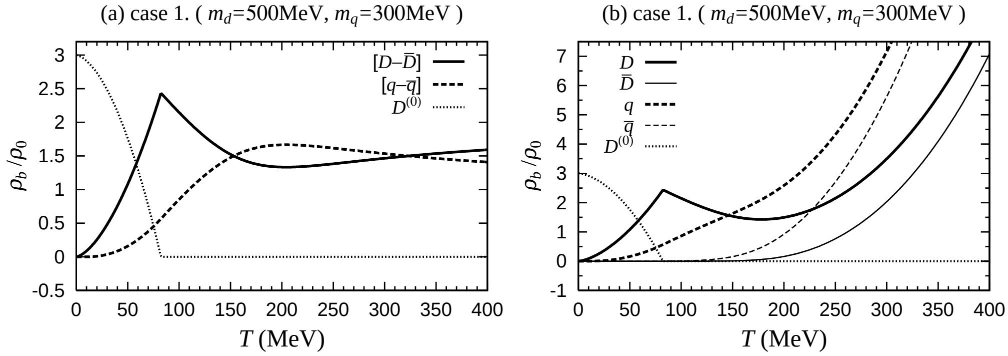

FIG. 6: T-dependence of the baryon-number densities (a) and the particle/antiparticle-number densities (b) for constituent quarks (case 1) at $\rho_b = 3\rho_0$. Lines q and $\bar{q}$ are for $\rho_{q,\bar{q}}$, and those D and $\bar{D}$ are for $\rho_{d,\bar{d}}^{(th)}$. Lines $[q - \bar{q}]$ and $[D - \bar{D}]$ are for $\rho_{b,q}$ and $\rho_{b,d}^{(th)}$. Line $D^{(0)}$ is for the condensed part $\rho_{b,d}^{(0)} = \rho_d^{(0)}$.

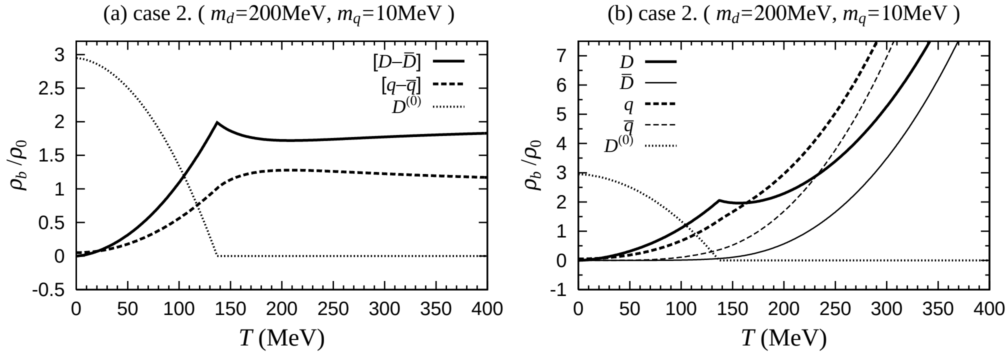

FIG. 7: T-dependence of the baryon-number densities (a) and the particle/antiparticle-number densities (b) for current quarks (case 2) at $\rho_b = 3\rho_0$. For conventions, see the caption of Fig. 6.

In Figs. 6 and 7, $\rho_d^{(0)}$ begins to be finite at a sufficiently low temperature showing BEC phase transition. It should be noticed in particular that the case 2 is diquark BEC in the unstable resonance state of the current quarks (35), which shows the stabilization of the resonance states in the matter through the equilibrium processes. The existence of the BEC is also confirmed in the saturation behavior of the quark chemical potential (Fig. 8); it shows that $\mu_q(= \mu_d/2)$ reaches the upper values $m_d/2$ at T_C and keeps this value in $T < T_C$.

In case 1, the diquark is in the bound state ($m_d < 2m_q$) and the association into the diquark ($q+q \rightarrow d$) gains the binding energy, which gives $\rho_{b,q} = 0$ at $T \rightarrow 0$; all quarks are combined into diquarks. In case

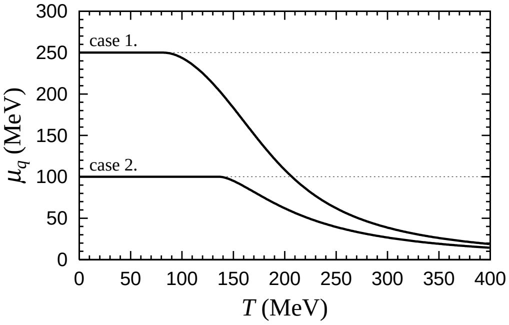

FIG. 8: Temperature dependences of quark chemical potentials in case 1 and 2.

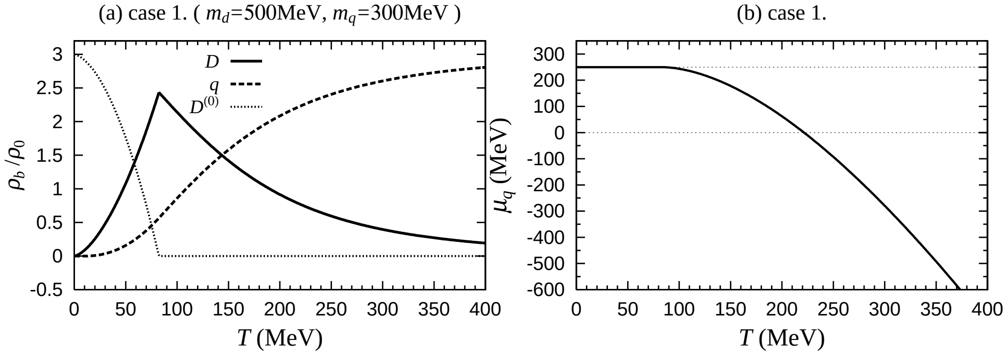
2, the diquark formation increases the total energy of the system because the diquark is a resonance state ($m_d > 2m_q$), and increase of the quark Fermi-energy (and also the entropy effect) competes with it. Balancing these effects, the system does not so much favor the pairing into bosonic molecules, and quarks still remain even at $T \simeq 0$ (Fig, 7a). These behaviors around zero temperature is generally discussed by using mass phase diagram (Fig. 3) in the previous subsection.

Now we turn to discussion for the high-T region. Taking case 1 first (Fig. 6b), we find that the thermal diquark density $\rho_d^{(th)}$ decreases from $T \sim 100\,\mathrm{MeV} \sim (2m_q - m_d)$, around which the dissociation should be effective, up to $T \sim 200\,\mathrm{MeV}$, but at this temperature the particle-antiparticle pair creations begin to occur, and then the diquark (and any other particle) density increases again. In case 2 (Fig. 7b), we also find the density increase that can be attributed to the pair creation effects. These diquark-density increases are very characteristic phenomena in the relativistic condensates. Really as shown in Fig. 9, in case of no antiparticle degrees of freedom, all composite molecules should dissociate into isolated fermions due to entropy enhancement.



(a) case 1. (m_d=500MeV, m_q=300MeV)

(b) case 1.

FIG. 9: Temperature dependences of the particle-number density (a) and quark chemical potential (b) in case of no antiparticle degrees of freedom. $(m_d, m_q) = (500, 300)\,\mathrm{MeV}$, $\rho_b = 3\rho_0$. For conventions, see Fig. 6.

Next we analyze asymptotic behaviors of the quark and diquark densities at the high-temperature limit. In Fig. 10a and b, the high-T behaviors are shown of the quark/diquark baryon-number densities in the case 1 and 2. From these figures, we can find a feature common in both cases: the ratio $\rho_{b,q}/\rho_{b,d} \to 1/2$ at $T \to \infty$. From the analysis given in Appendix B, we obtain a universal representation at the high-temperature limit:

$$R_{q/d} \equiv \left.\frac{\rho_{b,q}}{\rho_{b,d}}\right|_{T\to\infty} = \left(\frac{1}{g_c}\right)^2 \left(\frac{g_q}{g_d}\right) g_{st}, \tag{37}$$

$$g_c \cdot \mu_q \;\equiv\; \mu_d, \tag{38}$$

$$g_{st} \;\equiv\; \left\{\sum_{l=1}^{\infty} \frac{(-1)^{l-1}}{l^2}\right\} \Big/ \left\{\sum_{\acute{l}=1}^{\infty} \frac{(+1)^{\acute{l}-1}}{\acute{l}^2}\right\} = 1/2, \tag{39}$$

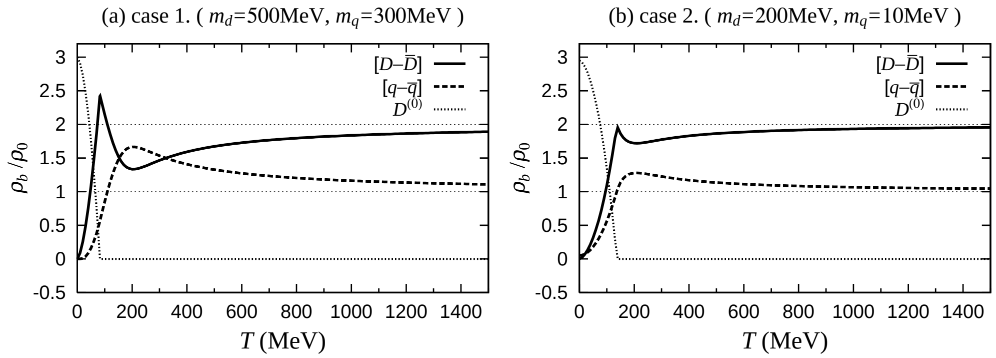


FIG. 10: Asymptotic behaviors of the quark/diquark baryon-number densities at large T and $\rho_b = 3\rho_0$ for case 1 (a) and 2 (b). For conventions, see Fig. 6.

where $g_{q,d}$ are the multiplicity factors for quark and diquark in the present system, which represent the degenerate degrees of freedom (color × flavor × spin). g_c is the composite factor indicating that a diquark is constructed by $g_c\times$quarks, and g_{st} is the statistical factor which reflects the statistical difference between quarks (fermions) and diquarks (bosons). In the present case, $g_q = 3 \cdot 2 \cdot 2$, $g_d = 3 \cdot 1 \cdot 1$, $g_c = 2$, and $g_{st} = 1/2$. With these values the ratio (37) becomes $R_{q/d} = 1/2$, which shows that the numerically obtained limit is universal, being independent of masses $m_{q,d}$.

As shown in Appendix B, the quantum statistics and the antiparticle degrees of freedom are essential in the derivation of the correct asymptotic limit (37). Especially existence of the statistical factor g_{st} in (37) implies that the quantum statistics still remains even in the high-temperature limit. This is understood that particles and antiparticles are drastically produced through the pair creation with large thermal energy, and Boltzmann region corresponding to high-temperature and dilute limits almost disappears.

Finally, we should mention consistency of the present method with real QCD at high temperature and density. Diquarks are dynamically-produced composite states by interquark interactions, which should be suppressed due to the asymptotic freedom in the high temperature and/or density. Furthermore, the Pauli blocking effect on the quark-quark interaction prevents quark pairs from forming composite diquarks, and the diquarks should become correlated pairs with a coherence length comparable with the interdiquark distance at the high density. Such effects of increasing density for pairing mechanism is referred as 'Mott effect' discussed with nuclear matter in refs. [37, 38]. Since nuclear force has a finite repulsive core in general, nuclear matter should undergo superfluid-normal phase transition at a specific density with short interparticle distance comparable to the range of the hard core, after the BEC-BCS crossover as density increases. QCD does not have such a specific scale of interaction length in the deconfinement phase, thus one can expect that the system is still in the superfluid phase even with infinite density at least around zero temperature. In this high density regime, however, diquarks as composite degrees become unessential with large coherence length as discussed above. Thus applicability of the present method should be restricted in relatively low-density region, and incorporation of these effects in some fashion is needed for extension to higher densities.

IV. EFFECTS OF INTERDIQUARK INTERACTIONS FOR DIQUARK BEC

The quarks and diquarks discussed in this paper should be quasiparticles in quark matter; the interaction effects are partially included in the existence itself of the composite states (diquark) and in the effective masses of the quasiparticles (quark and diquark). These effects have been included in the calculations in the previous subsections, so that they are not for the free quarks in the real meaning. However, we have still a missing effect, which are also not included in the Gaussian-type approximations [8, 9], that the quasiparticles can scatter into the different states through the residual interactions. In this subsection, we consider the diquark-diquark interaction within a mean-field approximation, and figure out its effects for the transition temperature of the diquark BEC.

As shown later, in the single-component boson systems, the boson-boson interaction effect does not change T_C from that of the free bose gas (A13) within the mean-field approximation [39]; it is consistent with the observed T_C of atomic BECs, which is rather a strongly interacting system [40]. The boson-boson correlation effects somewhat shift the value of T_C in the observed λ-transition of the liquid He^4:

$T_\lambda = 2.17\,\mathrm{K}$ (eq. (A13) gives $T_C = 3.1\,\mathrm{K}$), which is also shown in theoretical estimations [39, 41, 42, 43, 44]. In the diquark BEC, differently from the single-component boson system, the interaction effects are found to be effective for T_C still in the mean-field approximation through the chemical equilibrium process $(q + q \leftrightarrow d)$, so that the calculations in this level give a first-order approximation.

We start with a model of interacting color-$\bar{\mathbf{3}}$ scalar fields ϕ_α $(\alpha = 1, 2, 3)$ [41, 42], which represents the diquark degree of freedom:

$$L_{\text{eff}} = \partial_\mu \phi^\dagger \partial^\mu \phi - m_d^2 \phi^\dagger \phi - \lambda \left(\phi^\dagger \phi\right)^2, \tag{40}$$

where ϕ^4-term gives a diquark-diquark scattering effect (the Gross-Pitaevski approach). Here we have assumed that the higher-order scattering terms $(\phi^{6,8,\cdots})$ are renormalized into the two-body interaction [45]. It should be noted that the Ginzburg-Landau free-energy for the CSC phase also has a similar form [46, 47].

In the mean-field approximation, the interaction energy of the system is given by the expectation value of the interaction term in (40):

$$\begin{aligned}
\langle H_I \rangle &\equiv \langle \lambda \int d^3\mathbf{x} \phi_\alpha^\dagger(\mathbf{x}) \phi_\alpha(\mathbf{x}) \phi_\beta^\dagger(\mathbf{x}) \phi_\beta(\mathbf{x}) \rangle \\
&\to \lambda \int d^3\mathbf{x} \langle \phi_\alpha^\dagger(\mathbf{x}) \phi_\alpha(\mathbf{x}) \rangle \langle \phi_\beta^\dagger(\mathbf{x}) \phi_\beta(\mathbf{x}) \rangle \\
&= \frac{\lambda}{4V} \sum_{\mathbf{k},\mathbf{l},\alpha,\beta} \left[\frac{n_\mathbf{k}^\alpha n_\mathbf{l}^\beta}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} + \frac{2 n_\mathbf{k}^\alpha \bar{n}_\mathbf{l}^\beta}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} + \frac{\bar{n}_\mathbf{k}^\alpha \bar{n}_\mathbf{l}^\beta}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} + \frac{2 n_\mathbf{k}^\alpha}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} + \frac{2 \bar{n}_\mathbf{k}^\alpha}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} + \frac{1}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} \right],
\end{aligned} \tag{41}$$

where $n_\mathbf{k}^\alpha$ and $\bar{n}_\mathbf{k}^\alpha$ are the occupation numbers of the diquark and the antidiquark states with a color index α and a wave vector $\mathbf{k}$, and $\omega_\mathbf{k}^\alpha = \sqrt{\mathbf{k}^2 + m_d^2}$.

Now we consider the cases 1 and 2 in (35) just above T_C. In both cases, the antiquark densities can be neglected because T_C (a few tens MeV as in Figs. 4) is smaller than the diquark pair-creation energy $(2m_d = 400\,\mathrm{MeV} \sim 1\,\mathrm{GeV})$. We also keep the leading-order term for the particle-number density because we consider the high-density region [25]. Thus the interaction energy (41) becomes

$$\begin{aligned}
\langle H_I \rangle &\simeq \frac{\lambda}{4V} \sum_{\mathbf{k},\mathbf{l},\alpha,\beta} \frac{n_\mathbf{k}^\alpha n_\mathbf{l}^\beta}{\omega_\mathbf{k}^\alpha \omega_\mathbf{l}^\beta} \\
&\to \frac{\lambda}{4} \left[V \int \frac{d^3\mathbf{k} d^3\mathbf{l}}{(2\pi)^6} \frac{n_\mathbf{k} n_\mathbf{l}}{\omega_\mathbf{k} \omega_\mathbf{l}} + \int \frac{d^3\mathbf{k}}{(2\pi)^3} \frac{2 n_0 n_\mathbf{k}}{m_d \omega_\mathbf{k}} + \frac{1}{V} \left(\frac{n_0}{m_d} \right)^2 \right],
\end{aligned} \tag{42}$$

where $n_\mathbf{k} \equiv \sum_\alpha n_\mathbf{k}^\alpha$, and in the last line we have taken the continuum limit. It should be noted that, to manage the BEC singularity, we picked up the $\mathbf{k} = 0$ term n_0 from the $\mathbf{k}$ integrals in the continuum limit in (42). Eventually, the total energy of the system is given by

$$E_d = V \int \frac{d^3\mathbf{k}}{(2\pi)^3} \omega_\mathbf{k} (n_\mathbf{k} + \bar{n}_\mathbf{k}) + \langle H_I \rangle, \tag{43}$$

Differentiating with respect to $n_\mathbf{k}$, we obtain the single-particle energy:

$$\varepsilon_\mathbf{k} = \frac{(2\pi)^3}{V} \frac{\delta E_d}{\delta n(k)} = \sqrt{\mathbf{k}^2 + m_d^2} + \frac{B}{\sqrt{\mathbf{k}^2 + m_d^2}}, \tag{44}$$

$$B \equiv \frac{\lambda}{2} \left[\int \frac{d^3\mathbf{k}}{(2\pi)^3} \frac{n_\mathbf{k}}{\sqrt{\mathbf{k}^2 + m_d^2}} + \frac{n_0}{m_d V} \right]. \tag{45}$$

To evaluate (45), we concentrate on case of a small coupling constant and a large diquark mass; $B < m_d^2$. Generally we can say that this condition should be satisfied for small value of λ, but its exact evaluation is not easy so that we take it as a working hypothesis in the present paper. Under the condition $B < m_d^2$, eq. (44) has its minimum at $\mathbf{k} = 0$. More general arguments including wide range of λ and m_d will be made elsewhere.

As discussed in the previous subsection, for the sufficiently larger diquark mass m_d, the nonrelativistic approximation should be valid at the temperature close to T_C. In such a case, the occupation number

$n_{\mathbf{k}}$ (the Bose distribution function) should vanish for $k \gg m_d$, so that we can put $\sqrt{\mathbf{k}^2+m_d^2} \sim m_d$ in the first term of (45) in good approximation. Thus, we obtain the result:

$$\begin{aligned} \varepsilon_{\mathbf{k}} &\to \sqrt{\mathbf{k}^2+m_d^2}+\frac{\lambda}{2m_d^2}\left[\int \frac{d^3\mathbf{k}}{(2\pi)^3}n_{\mathbf{k}}+\frac{n_0}{V}\right] \\ &= \sqrt{\mathbf{k}^2+m_d^2}+\frac{\lambda}{2m_d^2}3\left(n_d^{(th)}+n_d^{(0)}\right), \end{aligned} \tag{46}$$

where $n_d^{(th)}$ and $n_d^{(0)}$ are the thermal and condensed densities of diquark. It should be noted that the antidiquark density $\bar{n}_{\mathbf{k}}$ has been dropped in (46) because it is less effective than that of diquark in the nonrelativistic approximation.

In the mean-field approximation, the single-particle energy appears, e.g., in the distribution functions as $\varepsilon_{\mathbf{k}}-\mu_d$, where the chemical potential μ_d is introduced as a Lagrange multiplier to the conserved baryon-number $Q=\int d^3\mathbf{x} j_0(\mathbf{x})$ with the baryon-number current $j_\mu = i(\phi^*\partial_\mu\phi - \phi\partial_\mu\phi^*)$ for the diquark degree of freedom. Using eq. (46), we obtain

$$\begin{aligned} \varepsilon_{\mathbf{k}}-\mu_d &= \sqrt{\mathbf{k}^2+m_d^2}+\frac{\lambda}{2m_d^2}3\left(n_d^{(th)}+n_d^{(0)}\right)-\mu_d \\ &= \sqrt{\mathbf{k}^2+m_d^2}-\mu_d^*, \end{aligned} \tag{47}$$

where the first term corresponds to the free-particle dispersion and the effective chemical potential μ_d^* is defined by

$$\mu_d^* \equiv \mu_d - \frac{\lambda}{2m_d^2}3\left(n_d^{(th)}+n_d^{(0)}\right), \tag{48}$$

which is a procedure of the chemical-potential renormalization [39].

With eq. (47), the boson distribution function (27) becomes

$$n_d = m_d^3 B_R(-\beta\mu_d^*, m_d\beta). \tag{49}$$

In this case, T_C is determined by the condition $\mu_d^* = m_d$ in (49): $n_d = m_d^3 B_R(-\beta m_d, m_d\beta)$, so that the formula for T_C itself with fixed n_d is completely the same as in the non-interacting bose gas; therefore T_C of single bose gas should not be changed at all through the chemical-potential renormalization [39]

Since we are considering the multi-component system with the chemical equilibrium ($q+q \leftrightarrow d$), the equilibrium condition (28) must hold for the bare chemical potentials $\mu_{q,d}$:

$$2\mu_q = \mu_d = \mu_d^* + \frac{\lambda}{2m_d^2}3\left(n_d^{(th)}+n_d^{(0)}\right). \tag{50}$$

In the equilibrium, this equation and the density constraint (25) should be solved with the Bose and Fermi distribution, (49) and (26). The transition temperature T_C is obtained by putting further condition $\mu_d^* = m_d$. It is clear that, differently from the single-component case, the interaction term in (50) gives a λ-dependence in T_C, which is the unique property of equilibrium system.

If the interaction is repulsive ($\lambda > 0$), it has an effect of decreasing the diquark density because the interaction term (46) gives the energy increase in the large diquark density, so that T_C gets lower with coupling strength λ. This is clearly found in Fig. 11, where the numerical results are given for the λ-dependence of T_C with the repulsive interaction in the cases 1 and 2 in (35).

The diquark-diquark interaction has been discussed for the color-$\bar{\mathbf{3}}$ diquarks by Donoghue and Sateesh [25], where the value of $\lambda = 60 \sim 100$ is estimated from the mass difference of the nucleon and Δ with the assumption of the quark-hadron continuity [25]. The positiveness of λ is also suggested in the P-matrix method [14].

Figs. 12 shows phase diagrams for the interacting diquark system with the suggested values $\lambda = 60 \sim 100$. From these results, we can expect that residual diquark-diquark interactions have the effect to lower T_C by $\sim 50\,\%$ in comparison with that in the non-interacting cases.

Here we should comment that the other interactions except the diquark-diquark one might give important effects, e.g., a possible quark-diquark interaction should generate baryonic collective modes in relation with three-quark correlations. As for these higher order correlations, we can discuss these effects by extending our method, referring to higher-order cluster expansion technique [10].

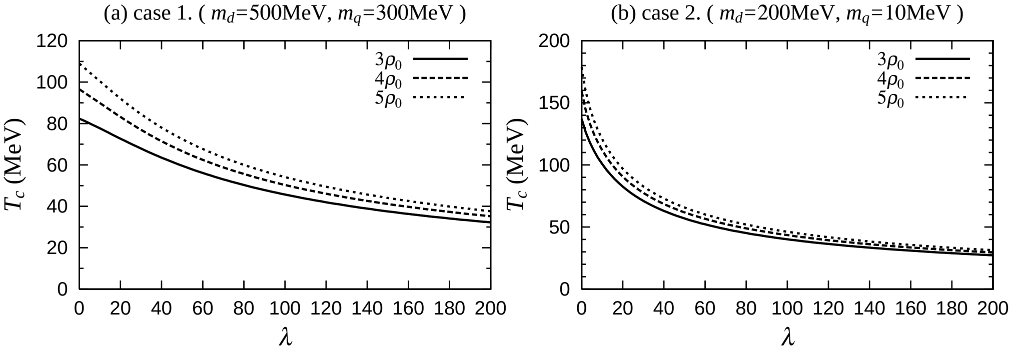

FIG. 11: Interdiquark-interaction dependence of T_C in case 1 (a) and 2 (b) for the several baryon-number densities. Coupling constant λ is defined in (40).

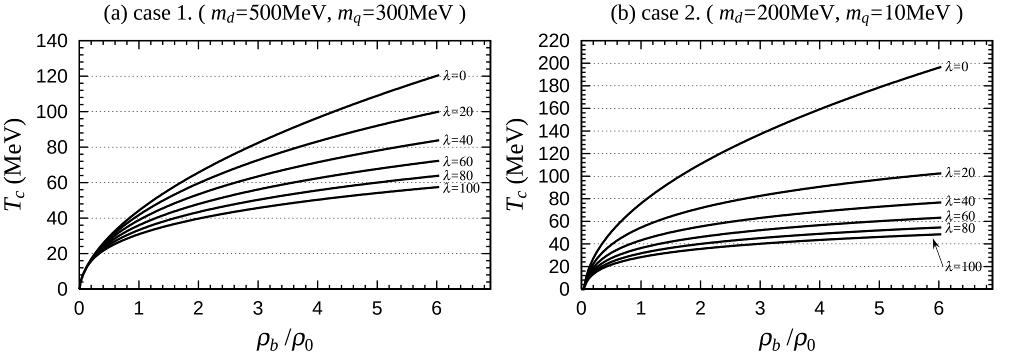

FIG. 12: Changes of T_C by the interdiquark-interaction effects in case 1 (a) and 2 (b) with the baryon-number densities. Coupling constant λ is defined in (40).

Finally we should discuss a possibility of the transition of quark matter into classical liquid with large volume exclusion. Schafroth, et al. [10] pointed out that the quasi-chemical equilibrium theory cannot be applied to the interacting fermionic system which undergoes the condensation into the classical liquid before the formation of difermion molecules. To evaluate it for quark matter we now estimate the de Boer parameter Λ^* [48] which gives the ratio of the quantum energy fluctuation to the potential depth ε:

$$\Lambda^* = \frac{h}{\sigma\sqrt{m\varepsilon}} = \frac{(\hbar c)2\pi}{\sigma\sqrt{mc^2\varepsilon}}, \tag{51}$$

where σ is a range of interaction and m is a particle mass. Large Λ^* corresponds to large quantum fluctuation relative to the potential depth ε. Taking typical values of several parameters for quark matter; $\sigma \sim O(1)$fm, $mc^2 \sim O(10)$MeV, $\varepsilon \sim O(10)$MeV, Λ^* is roughly estimated to be $O(10^2)$ which is very large relative to that of the quantum liquid He^4 ($\Lambda^* \sim 2.64$). This large quantum fluctuation implies that quark matter cannot be condensed into classical liquid and it must be a quantum gas or, rather, quantum liquid. As qualitative feature of liquid He^4 can be well described by free bose gas model calculations, we expect, in this sense, the quasi-chemical equilibrium picture should be applicable for quark matter.

V. SUMMARY AND OUTLOOK

We have generally developed the quasi-chemical equilibrium theory for the system of isolated fermions and composite bosons of fermion pairs in the relativistic framework, and derived the conditions for occurrence of the composite-boson BEC. Especially a general property of BEC in a multi-component system is suggested; only the lightest composite bosons can be condensed to the BEC state (one-BEC theorem).

An application has been done for the diquark condensates in quark matter at moderate densities, and only 2SC-type diquarks are treated by virtue of the one-BEC theorem. In this framework we have discussed the color superconductivity as the diquark BEC in a possible BCS-BEC crossover regime. We found the mass phase diagrams which determine the occurrence of BEC at a certain temperature for various mass values of quarks and diquarks. With phenomenological values of model parameters, we obtain T_C as a few tens MeV, which is lower than those by model calculations within mean-field approximations, $\sim O(100)\,\mathrm{MeV}$. In any case, T_C has a large dependence on quark and diquark masses, and it varies from 0 to ∞ along with $m_d \to 0$ (strong coupling limit).

At the high-T limit, antiparticles produced through the pair-creation processes suppress the dissociation of diquarks into quark pairs, and the ratio of the number densities are found to approach a universal value $R_{q/d} = 1/2$, which reflects that quantum statistics still remains even in the high-T limit.

We have also discussed effects of the diquark-diquark interaction, and found within the mean-field approximation that a possible repulsive interaction lowers T_C by $\sim 50\,\%$ in comparison with that of non-interacting case through a chemical-potential renormalization.

The other correlation effects beyond the mean-field approximation, e.g., quark-diquark and three-quark correlations, should also be important in the BCS-BEC crossover problem. Combining the method of the Beth-Uhlenbeck approach [37] with the present quasi-chemical equilibrium theory, we should discuss the correlation effects and the crossover problem from less model-dependent point of view. The study along this line is now ongoing and will be presented near future.

APPENDIX A: ANALYSIS OF BEC-TRANSITION TEMPERATURE

In this appendix, we derive some formulas on the critical temperature of the BEC transition for single bose gas in the three limiting cases: 1) nonrelativistic limit, 2) ultrarelativistic limit with a mass correction, and 3) ultrarelativistic limit with negative-charge particles (antibosons).

Here we consider the function B_R defined in (7), the denominator of which can be expanded as

$$\begin{aligned} B_R(-\tilde{\beta}\tilde{\mu}_B, \tilde{\beta}) &\equiv \frac{1}{2\pi^2}\int_0^\infty \frac{\cosh\theta(\sinh\theta)^2}{e^{\tilde{\beta}(\cosh\theta-\tilde{\mu}_B)}-1}d\theta \\ &= \frac{1}{2\pi^2}\sum_{l=1}^\infty e^{l\tilde{\beta}\tilde{\mu}_B}\int_0^\infty e^{-l\tilde{\beta}\cosh\theta}\cosh\theta(\sinh\theta)^2 d\theta, \end{aligned} \tag{A1}$$

where $\tilde{\mu}_B = \mu_B/m$. The integral in the above expansion is evaluated to be

$$\begin{aligned} \int_0^\infty e^{-l\tilde{\beta}\cosh\theta}\cosh\theta(\sinh\theta)^2 d\theta &= \frac{1}{4}\int_0^\infty e^{-l\tilde{\beta}\cosh\theta}[\cosh(3\theta)-\cosh\theta]d\theta \\ &= \frac{1}{4}\left\{K_3(l\tilde{\beta}) - K_1(l\tilde{\beta})\right\} = \frac{1}{l\tilde{\beta}}K_2(l\tilde{\beta}), \end{aligned} \tag{A2}$$

where $K_\nu(z)$ is the modified Bessel function:

$$K_\nu(z) = \int_0^\infty e^{-z\cosh\theta}\cosh(\nu\theta)d\theta, \tag{A3}$$

and we have used a formula: $K_{\nu-1}(z) - K_{\nu+1}(z) = -(2\nu/z)K_\nu(z)$ [49]. Substituting eq. (A2) into (A1), We obtain

$$B_R(-\tilde{\beta}\tilde{\mu}_B, \tilde{\beta}) = \frac{1}{2\pi^2}\sum_{l=1}^\infty \frac{e^{l\tilde{\beta}\tilde{\mu}_B}}{l\tilde{\beta}}K_2(l\tilde{\beta}). \tag{A4}$$

The transition temperature $\tilde{\beta}_C = m_B/T_C$ is obtained from eq. (5) with $\tilde{\mu}_B = \mu_B/m_B = 1$, so that

$$n_B = m_B^3 B_R(-\tilde{\beta}_C, \tilde{\beta}_C) = \frac{m_B^3}{2\pi^2} \sum_{l=1}^{\infty} \frac{e^{l\tilde{\beta}_C}}{l\tilde{\beta}_C} K_2(l\tilde{\beta}_C). \tag{A5}$$

Using the asymptotic expansion of $K_\nu(z)$ for $z \to \infty$ [49]:

$$K_\nu(z) \sim \sqrt{\frac{\pi}{2z}} e^{-z} \sum_{k=0}^{\infty} \frac{\Gamma\left(\nu + k + \frac{1}{2}\right)}{\Gamma\left(\nu - k + \frac{1}{2}\right)} \frac{(2z)^{-k}}{k!}, \tag{A6}$$

we obtain the asymptotic expansion of (A5) for large $\tilde{\beta}_C$ (small T_C):

$$n_B = \frac{1}{\lambda_{T_C}^3} \sum_{k=0}^{\infty} \frac{\Gamma\left(\frac{5}{2} + k\right)}{\Gamma\left(\frac{5}{2} - k\right)} \frac{\zeta\left(k + \frac{3}{2}\right)}{k!} (2\tilde{\beta}_C)^{-k}, \tag{A7}$$

where $\lambda_T = \sqrt{2\pi\tilde{\beta}/m_B^2}$ is the thermal de Broglie wave length and the ζ-function is defined by $\zeta(z) = \sum_{l=1}^{\infty} l^{-z}$. Taking the first term in the right-hand side of (A7), we obtain the nonrelativistic limit for T_C [32]:

$$n_B \lambda_{T_C}^3 \sim \zeta(3/2) \sim 2.612. \tag{A8}$$

To obtain the ultrarelativistic limit, we use the asymptotic expansion of $K_n(z)$ with positive integer n for $z \to 0$:

$$K_n(z) \sim \frac{1}{2} \sum_{k=0}^{n-1} (-1)^k \frac{(n-k-1)!}{k!} \left(\frac{z}{2}\right)^{2k-n}. \tag{A9}$$

Taking the first term of the above expansion and using it for (A5), we obtain the density formula for small $\tilde{\beta}_C$:

$$n_B \sim \frac{m_B^3}{\pi^2} \sum_{l=1}^{\infty} \frac{e^{l\tilde{\beta}_C}}{(l\tilde{\beta}_C)^3} = \frac{m_B^3}{\pi^2 \tilde{\beta}_C^3} B_3(-\tilde{\beta}_C), \tag{A10}$$

where $B_\alpha(\nu)$ is the Appell function:

$$B_\alpha(\nu) = \frac{1}{\Gamma(\alpha)} \int_0^\infty \frac{z^{\alpha-1} dz}{e^{z+\nu} - 1} = \sum_{l=1}^{\infty} \frac{e^{-l\nu}}{l^\alpha}. \tag{A11}$$

Using the expansion $B_3(-\tilde{\beta}_C) \sim \zeta(3) + \zeta(2)\tilde{\beta}_C$ for $\tilde{\beta}_C \to 0$ (high-T_C limit) in eq. (A10), we obtain the ultrarelativistic limit for T_C:

$$\begin{aligned} n_B &\sim \frac{m_B^3}{\pi^2} \left[\frac{\zeta(3)}{\tilde{\beta}_C^3} + \frac{\zeta(2)}{\tilde{\beta}_C^2} \right] \\ &= \frac{\zeta(3)}{\pi^2} T_C^3 + m_B \frac{\zeta(2)}{\pi^2} T_C^2, \end{aligned} \tag{A12}$$

where $\zeta(2) = \pi^2/6 \sim 1.6449$ and $\zeta(3) \sim 1.2020$. It should be noted that the first term in the above equation does not include m_B; in the ultrarelativistic limit, the boson mass is neglected and the energy-momentum dispersion relation is approximated to be $\varepsilon \sim |\mathbf{k}|$. The second term in eq. (A12) corresponds to the small mass correction.

In summary, we obtain the formulas of T_C of the relativistic BEC:

$$T_C \sim \begin{cases} 3.313 \frac{n_B^{2/3}}{m_B}, & \text{(nonrelativistic limit)} \\ 2.017 n_B^{1/3}. & \text{(ultrarelativistic limit)} \end{cases} \tag{A13}$$

Finally we consider the boson-antiboson system, where the similar calculation with (15) gives the expansion for baryon-number density :

$$n_{b,B} = n_B - n_{\bar{B}} = \frac{m_B^3}{\pi^2} \sum_{l=1}^{\infty} \frac{\sinh(l\tilde{\beta}\tilde{\mu}_B)}{l\tilde{\beta}} K_2(l\tilde{\beta}). \tag{A14}$$

The formula for T_C is obtained by putting $\tilde{\mu}_B = 1$ and $\tilde{\beta} = \tilde{\beta}_C$. Using eq. (A6), we obtain the asymptotic expansion for large $\tilde{\beta}_C$:

$$n_{b,B} = \frac{1}{\lambda_{T_C}^3} \sum_{k=0}^{\infty} \frac{\Gamma\left(\frac{5}{2}+k\right)}{\Gamma\left(\frac{5}{2}-k\right)} \frac{1}{k!} \left\{ \zeta\left(k+\frac{3}{2}\right) - B_{k+3/2}(2\tilde{\beta}_C) \right\} (2\tilde{\beta}_C)^{-k}, \tag{A15}$$

where $B_{k+3/2}$, defined by (A11), corresponds to the antiboson contributions. In the nonrelativistic limit (low T_C), $B_{k+3/2}(2\beta_C)$ can be neglected because $B_\alpha(z) \sim e^{-z}$, so that we obtain the same formula as eqs. (A7,A8) where n_B is replaced with $n_{b,B}$. This means that the antiboson degree of freedom is suppressed and we can put $n_{b,B} \sim n_B$ in this limit.

In the ultrarelativistic limit (small $\tilde{\beta}_C$), using (A9), eq. (A14) becomes

$$n_{b,B} \sim \frac{2m_B^3}{\pi^2} \zeta(2) \frac{\tilde{\mu}_B}{\tilde{\beta}^2} = \frac{2}{\pi^2} \zeta(2) \mu_B T^2, \tag{A16}$$

where $\sinh z/z \sim 1$ has been used. Substituting $\tilde{\mu}_B = 1$ and $\tilde{\beta} = \tilde{\beta}_C$, we obtain the ultrarelativistic formula for T_C:

$$n_{b,B} \sim \frac{2m_B^3}{\pi^2} \frac{\zeta(2)}{\tilde{\beta}_C^2} = 2m_B \frac{\zeta(2)}{\pi^2} T_C^2. \tag{A17}$$

Comparison with eq. (A12) shows that the leading terms from $n_{B,\bar{B}}$ cancels out so that the result depend on m_B in spite of the ultrarelativistic limit.

In summary, we obtain the formulas of T_C for the boson-antiboson system:

$$T_C \sim \begin{cases} 3.313 \frac{n_{b,B}^{2/3}}{m_B}, & \text{(nonrelativistic limit)} \\ 1.732 \sqrt{\frac{n_{b,B}}{m_B}}. & \text{(ultrarelativistic limit)} \end{cases} \tag{A18}$$

APPENDIX B: ASYMPTOTIC FORM OF DENSITY PROFILES

First we calculate the asymptotic expansion of fermion-number density; calculations go in the same way as for the boson density formula (A14):

$$n_{b,F} = n_F - n_{\bar{F}} = \frac{m_F^3}{\pi^2} \sum_{l=1}^{\infty} (-1)^{l-1} \frac{\sinh(l\tilde{\beta}\tilde{\mu}_F)}{l\tilde{\beta}} K_2(l\tilde{\beta}), \tag{B1}$$

where the extra factor $(-1)^{l-1}$ comes from the factor $+1$ in the denominator of the fermion-density (8) reflecting Fermi statistics (Bose statistics gives the extra factor $(+1)^{l-1} = +1$ which is embedded in eq. (A14)). Expanding the function K_2 and taking the leading-order term in (A9), we obtain the fermion-density formula for small $\tilde{\beta}$:

$$n_{b,F} \sim \frac{2m_F^3}{\pi^2} \frac{\zeta(2)}{2} \frac{\tilde{\mu}_F}{\tilde{\beta}^2} = \frac{2}{\pi^2} \frac{\zeta(2)}{2} \mu_F T^2, \tag{B2}$$

where $\sum_{l=1}^{\infty} (-1)^{l-1}/l^\alpha = (1 - 2^{1-\alpha})\zeta(\alpha)$ has been used to give the factor $\zeta(2)/2$ in (B2). In case of Bose statistics, factor $\sum_{l=1}^{\infty} (+1)^{l-1}/l^\alpha = \zeta(\alpha)$ from the analysis of eq. (A14) gives $\zeta(2)$ in (A16). The difference between the factors $\zeta(2)$ and $\zeta(2)/2$ in eqs. (A16,B2) tells that the effect of quantum statistics still remains even in high-T limit, which is discussed in eq. (37).

Now we apply the boson and fermion density-formulas for high-T region, (A16) and (B2), to quark-diquark system, and evaluate the high-T limit of the baryon-number density ratio. Using eqs. (A16,B2), the baryon-density ratio of isolated quarks to diquarks is given by

$$R_{q/d} \equiv \frac{\rho_{b,q}}{\rho_{b,d}}\bigg|_{T\to\infty} = \frac{(1/3)g_q n_{b,q}}{(2/3)g_d n_{b,d}}\bigg|_{T\to\infty} = \left(\frac{1}{g_c}\right)^2 \left(\frac{g_q}{g_d}\right) g_{st}, \tag{B3}$$

$$g_c \cdot \mu_q \equiv \mu_d, \tag{B4}$$

$$g_{st} \equiv \left\{\sum_{l=1}^{\infty} \frac{(-1)^{l-1}}{l^2}\right\} \Big/ \left\{\sum_{\acute{l}=1}^{\infty} \frac{(+1)^{\acute{l}-1}}{\acute{l}^2}\right\} = 1/2, \tag{B5}$$

where $1/3, 2/3$ are the baryon numbers of quark and diquark, and $g_{q,d}$ are the multiplicity factors for quark and diquark in the present system, which represent the degenerate degrees freedom (color × flavor × spin). g_c is the composite factor indicating that a diquark is constructed by $g_c\times$quarks (in the present case, $g_c = 2$), and g_{st} is the statistical factor which reflects the statistical difference between quarks (fermions) and diquarks (bosons).
